#### Abstract

The Space Shuttle avionics software represents a successful integration of many of the computer industry's most advanced software engineering practices and approaches. Beginning in the late 1970's this software development and maintenance project has evolved one of the world's most mature software processes applying the principles of the highest levels of the Carnegie Mellon University Software Engineering Institute's Capability Maturity Model, Trusted Software Methodology, and ISO 9001 Standards. This software process, considered to be a "best practice" by many software industry organizations includes state-of-the-practice software reliability engineering methodologies. Life-critical Shuttle avionics software produced by this process is recognized to be among the highest quality and highest reliability software in operation in the world. This case study explores the successful use of extremely detailed fault and failure history, throughout the software life cycle, in the application of software reliability engineering techniques to gain insight into the flight-worthiness of the software and to suggest "where to look" for remaining defects. The role of software reliability models and failure prediction techniques is examined and explained to allow the use of these approaches on other software projects. One of the most important aspects of such an approach -- "how to use and interpret the results" of the application of such techniques -- is addressed.

Keywords: Verification and validation, software reliability measurement and prediction, safety critical software, risk analysis.

### Space Shuttle Flight Software Application

The Space Shuttle Primary Avionics Software Subsystem (PASS) represents a successful integration of many of the computer industry's most advanced software engineering practices and approaches. Beginning in the late 1970's this software development and maintenance project has evolved one of the world's most mature software processes applying the principles of the highest levels of the Software Engineering Institute's Capability Maturity Model and ISO 9001 Standards. This software process, considered to be a "best practice" by many software industry organizations includes state-of-the-practice software reliability engineering (SRE) methodologies. Life-critical PASS produced by this process is recognized to be among the highest quality and highest reliability software in operation in the world. Using this application, we show how SRE can be applied to: interpret software reliability predictions, support verification and validation of the software, assess the risk of deploying the software, predict the reliability of the software, develop test strategies to bring the software into conformance with reliability specifications, and make reliability decisions regarding deployment of the software.

Reliability predictions are currently used by Lockheed-Martin Space Information Systems to add confidence to established positions regarding low failure probabilities for the PASS that are based on formal software certification processes. It is the purpose of this case study to share the experience obtained from the use of SRE on this project, since this application is judged by the Lockheed-Martin team to be a successful attempt to apply SRE to this software. The SRE techniques and concepts employed by Lockheed-Martin should be of value for other software systems.

### **Interpretation of Software Reliability Predictions**

Successful use of statistical modeling in predicting the reliability of a software system requires a thorough understanding of precisely how the resulting predictions are to be interpreted and applied [9]. The PASS (430 KLOC) is frequently modified, at the request of NASA, to add or change capabilities using a constantly improving process. Each of these successive PASS versions constitutes an upgrade to the preceding software version. Each new version of the PASS (designated as an Operational Increment, OI) contains software code which has been carried forward from each of the previous versions ("previous-version subset") as well as new code generated for that new version ("new-version subset"). We have found that by applying a reliability model independently to the code subsets according to the following rules, we can obtain satisfactory composite predictions for the total version:

- all new code developed for a particular version does use a nearly constant process.
- (2) all code introduced for the first time for a particular version does, as an aggregate, build up the same "shelflife" and operational execution history.
- (3) unless subsequently changed for a newer capability, thereby becoming "new code" for a later version, all new code is only changed thereafter to correct faults.

It is essential to recognize that this approach requires a very accurate code change history so that every failure can be uniquely attributed to the version in which the defective line(s) of code were first introduced. In this way it is possible to build a separate failure history for the new code in each release. To apply SRE to your software system you should consider breaking your systems and processes down into smaller elements to which a reliability model can be more accurately applied. Using this approach, we have been successful in applying SRE to predict the reliability of the PASS for NASA.

Estimating Execution Time. We estimate execution time of segments of the PASS software by analyzing records of test cases in digital simulations of operational flight scenarios as well as records of actual use in *Shuttle* operations. Test case executions are only counted as "operational execution time" for previous-version subsets of the version being tested if the simulation fidelity very closely matches actual operational conditions. Pre-release test execution time for the new code actually being tested in a version is never counted as operational execution time. We use the failure history and operational execution time history for the new-code subset of each version to generate an individual reliability prediction for that new code in each version by separate applications of the reliability model. This approach places every line of code in

the total PASS into one of the subsets of "newly" developed code, whether "new" for the original version or any subsequent version. We then represent the total reliability of the entire software system as that of a composite system of separate components ("new-code subsets"), each having an individual execution history and reliability, connected in series. Lockheed-Martin is currently using this approach to apply the *Schneidewind* [8,9] model as a means of predicting a "conservative lower bound" for the PASS reliability.

Interpretations and Credibility. The two most critical factors in establishing credibility in software reliability predictions are the validation method and the way the predictions are interpreted. For example, a "conservative" prediction can be interpreted as providing an "additional margin of confidence" in the software reliability, if that predicted reliability already exceeds an established "acceptable level" or requirement. You may not be able to validate that you can predict the reliability of your software precisely, but you can demonstrate that with "high confidence" you can predict a lower bound on the reliability of that software within a specified environment. If you can use historical failure data at a series of previous dates (and you have the actual data for the failure history following those dates), you should be able to compare the predictions to the actual reliability and evaluate the performance of the model(s) used. You should take all these factors into consideration as you establish validation success criteria. This will also significantly enhance the credibility of your predictions among those who must make decisions based on your results.

## Verification and Validation

Software reliability measurement and prediction are useful approaches to verify and validate software. Measurement refers to collecting and analyzing data about the observed reliability of software, for example the occurrence of failures during test. Prediction refers to using a model to forecast future software reliability, for example failure rate during operation. Measurement also provides the failure data that is used to estimate the parameters of reliability models (i.e., make the best fit of the model to the observed failure data). Once the parameters have been estimated, the model is used to predict the future reliability of the software. Verification ensures that the software product, as it exists in a given project phase, satisfies the conditions imposed in the preceding phase (e.g., reliability measurements of safety critical software components obtained during test conform to reliability specifications made during design) [5]. Validation ensures that the software product, as it exists in a given project phase, which could be the end of the project, satisfies requirements (e.g., software reliability predictions obtained during test correspond to the reliability specified in the requirements) [5].

Another way to interpret verification and validation is that it builds confidence that software is ready to be released for operational use. The release decision is crucial for systems in which software failures could endanger the safety of the mission and crew (i.e., safety critical software). To assist in making an informed decision, we integrate software risk analysis and reliability prediction, and we are evaluating stopping rules for testing. This approach is applicable to all safety critical software. Improvements in the reliability of software, where the reliability measurements and predictions are directly related to mission and safety, contribute to system safety.

Reliability Measurements and Predictions. There are a number of measurements and predictions that can be made of reliability to verify and validate the software. Among these are remaining failures, maximum failures, total test time required to attain a given fraction of remaining failures, and time to next failure. These have been shown to be useful measurements and predictions for: 1) providing confidence that the software has achieved reliability goals; 2) rationalizing how long to test a software component (e.g., testing sufficiently long to verify that the measured reliability conforms to design specifications); and 3) analyzing the risk of not achieving remaining failure and time to next failure goals [6]. Having predictions of the extent to which the software is not fault free (remaining failures) and whether a failure it is likely to occur during a mission (time to next failure) provide criteria for assessing the risk of deploying the software. Furthermore, fraction of remaining failures can be used as both an operational quality goal in predicting total test time requirements and, conversely, as an indicator of operational quality as a function of total test time expended [6].

The various software reliability measurements and predictions can be divided into the following two categories to use in combination to assist in assuring the desired level of reliability of the software in safety critical systems like the PASS. The two categories are: 1) measurements and predictions that are associated with residual software faults and failures, and 2) measurements and predictions that are associated with the ability of the software to complete a mission without experiencing a failure of a specified severity. In the first category are: remaining failures, maximum failures, fraction of remaining failures, and total test time required to attain a given number or fraction of remaining failures. In the second category are: time to next failure and total test time required to attain a given time to next failure. In addition, there is the risk associated with not attaining the required remaining failures and time to next failure. Lastly, there is operational quality which is derived from fraction of remaining failures. With this type of information a software manager can determine whether more testing is warranted or whether the software is sufficiently tested to allow its release

or unrestricted use. These predictions provide a quantitative basis for achieving reliability goals [2].

#### Risk Assessment

Safety Risk pertains to executing the software of a safety critical system where there is the chance of injury (e.g., astronaut injury or fatality), damage (e.g., destruction of the Shuttle), or loss (e.g., loss of the mission) if a serious software failure occurs during a mission. In the case of the Shuttle PASS, where the occurrence of even trivial failures is extremely rare, the fraction of those failures that pose any safety or mission success impact is too small to be statistically significant. As a result, for this approach to be feasible, all failures (of any severity) over the entire 20 year life of the project have been included in the failure history data base for this analysis. Therefore, the risk criterion metrics to be discussed for the Shuttle quantify the degree of risk associated with the occurrence of any software failure, no matter how insignificant it may be. The approach used can be applied to Safety Risk where sufficient data exist.

We are experimenting with an algorithm which uses of the Schneidewind Software Reliability Model to compute a parameter: fraction of remaining failures as a function of the archived failure history during test and operation [6]. The prediction methodology uses this parameter and other reliability quantities to provide bounds on total test time, remaining failures, operational quality, and time to next failure that are necessary to meet arbitrarily defined Shuttle software reliability levels. The total test time versus fraction of remaining failures curve shows a pronounced asymptotic characteristic that indicates the possibility of big gains in reliability as testing continues; eventually the gains become marginal as testing continues.

Two criteria for software reliability levels will be defined. Then these criteria will be applied to the risk analysis of safety critical software, using the PASS as an example. In the case of the Shuttle example, the "risk" will represent the degree to which the occurrence of failures does not meet required reliability levels, regardless of how insignificant the failures may be. Next, a variety of prediction equations that are used in reliability prediction and risk analysis will be defined and derived; included is the relationship between time to next failure and reduction in remaining failures. Then it is shown how the prediction equations can be used to integrate testing with reliability and quality. An example is shown of how the risk analysis and reliability predictions can be used to make decisions about whether the software is ready to deploy; this approach could be used to determine whether a software system is safe to deploy.

# Criteria for Reliability

If the reliability goal is the reduction of failures that would cause loss of a specified severity to an acceptable level of risk [7], then for software to be ready to deploy, after having been tested for total time t, it must satisfy the following criteria:

1) predicted remaining failures 
$$r(t_i) < r_c$$
, (1)

where re is a specified critical value, and

2) predicted time to next failure 
$$T_F(t_t) > t_m$$
, (2)

where t<sub>m</sub> is mission duration.

The total time t could represent a Safe/Unsafe criterion, or the time to remove all faults regardless of severity (as used in the *Shuttle* example).

For systems that are tested and operated continuously like the *Shuttle*,  $t_t$ ,  $T_F(t_t)$ , and  $t_m$  are measured in execution time. Note that, as with any methodology for assuring software reliability, there is no guarantee that the expected level will be achieved. Rather, with these criteria, the objective is to reduce the risk of deploying the software to a "desired" level.

Remaining Failures Criterion. Using the assumption that the faults that cause failures are removed (this is the case for the Shuttle), criterion 1 specifies that the residual failures and faults must be reduced to a level where the risk of operating the software is acceptable. As a practical matter, r<sub>c</sub>=1 is suggested. That is, the goal is to reduce the expected remaining failures of a specified severity to less than one before deploying the software. The assumption for this choice is that one or more remaining failures would constitute an undesirable risk of failures of the specified severity. Thus, one way to specify r<sub>e</sub> is by failure severity level (e.g., include only life threatening failures). Another way, which imposes a more demanding criterion, is to specify that r<sub>a</sub> represents all severity level, as in the Shuttle example. For example,  $r(t_i)<1$  would mean that r(t<sub>i</sub>) must be less than one failure, independent of severity level.

If  $r(t_i) \ge r_c$  is predicted, testing would continue for a total time  $t_i' \ge t_i$  that is predicted to achieve  $r(t_i') < r_c$ , using the assumption that more failures will be experienced and more faults will be corrected so that the *remaining failures* will be reduced by the quantity  $r(t_i) - r(t_i')$ . If the developer does not have the resources to satisfy the criterion or is unable to satisfy the criterion through additional testing, the risk of deploying the software prematurely should be assessed (see the next section). It is known that it is impossible to demonstrate the absence of faults [3]; however the risk of failures occurring can be reduced to an acceptable level, as represented by  $r_c$ . This scenario is shown in Figure 1. In *case*  $A r(t_i) < r_c$  is

predicted and the mission begins at  $t_t$ . In case B  $r(t_t) \ge r_e$  is predicted and the mission could be postponed until the software is tested for total time  $t_t$  when  $r(t_t') < r_e$  is predicted. In both cases *criterion 2*) might also be required for the mission to begin.

Time to Next Failure Criterion. Criterion 2 specifies that the software must survive for a time greater than the duration of the mission. If  $T_r(t_i) \le t_m$ , is predicted, the software is tested for a total time t,">t, that is predicted to achieve  $T_{r}(t,")>t_{m}$ using the assumption that more failures will be experienced and faults corrected so that the time to next failure will be increased by the quantity  $T_F(t_i)$ - $T_F(t_i)$ . Again, if it is infeasible for the developer to satisfy the criterion for lack of resources or failure to achieve test objectives, the risk of deploying the software prematurely should be assessed (see the next section). This scenario is shown in Figure 2. In case A  $T_{\rm r}(t_{\rm r}) > t_{\rm r}$  is predicted and the mission begins at t. In case B  $T_r(t_i) \le t_m$  is predicted and in this case the mission could be postponed until the software is tested for total time t," when  $T_r(t_i^n) > t_m$  is predicted In both cases criterion 1) might also be required for the mission to begin. If neither criterion is satisfied, the software is tested for a time which is the greater of t,' or t,".

Total Test Time. The amount of total test time t, can be considered a measure of the degree to which software reliability goals have been achieved. This is particularly the case for systems like the Shuttle where the software is subjected to continuous and rigorous testing for several years in multiple facilities, using a variety of operational and training scenarios (e.g., by Lockheed-Martin in Houston, by NASA in Houston for astronaut training, and by NASA at Cape Canaveral). We can view t, as an input to a risk reduction process, and  $r(t_1)$  and  $T_r(t_1)$  as the outputs, with  $r_c$ and t<sub>m</sub> as "risk criteria levels" of reliability that control the process. While it must be recognized that total test time is not the only consideration in developing test strategies and that there are other important factors, like the consequences for reliability and cost, in selecting test cases [11] nevertheless, for the foregoing reasons, total test time has been found to be strongly positively correlated with reliability growth for the Shuttle [9].

Remaining Failures. The mean value of the risk criterion metric (RCM) for criterion 1 is formulated as follows:

RCM 
$$r(t_i) = (r(t_i) - r_c)/r_c = (r(t_i)/r_c) - 1$$
 (3)

Equation (3) is plotted in Figure 3 as a function of t, for  $r_c=1$ , where *positive*, zero, and negative values correspond to  $r(t_t) > r_c$ ,  $r(t_t) = r_c$ , and  $r(t_t) < r_c$ , respectively. In Figure 3, these values correspond to the following regions: CRITICAL (i.e., above the X-axis predicted remaining failures are greater than the specified value); NEUTRAL (i.e., on the X-axis

predicted remaining failures are equal to the specified value); and DESIRED (i.e., below the X-axis predicted remaining failures are less than the specified value, which could represent a "safe" threshold or in the Shuttle example, an "error-free" condition boundary). This graph is for the Shuttle Operational Increment OID (with many years of shelf life): a software system comprised of modules and configured from a series of builds to meet Shuttle mission functional requirements. In this example it can be seen that at approximately t<sub>i</sub>=57 the risk transitions from the CRITICAL region to the DESIRED region.

**Time to Next Failure.** Similarly the mean value of the *risk* criterion metric (RCM) for criterion 2 is formulated as follows:

RCM 
$$T_F(t_t) = (t_m - T_F(t_t))/t_m = 1 - (T_F(t_t))/t_m$$
 (4)

Equation (4) is plotted in Figure 4 as a function of  $t_n$  for  $t_m$ =8 days (a typical mission duration time for this OI), where positive, zero, and negative risk corresponds to  $T_F(t_i) < t_m$ ,  $T_F(t_i) = t_m$ , and  $T_F(t_i) > t_m$ , respectively. In Figure 4, these values correspond to the following regions: CRITICAL (i.e., above the X-axis predicted time to next failure is less than the specified value); NEUTRAL (i.e., on the X-axis predicted time to next failure is equal to the specified value); and DESIRED (i.e., below the X-axis predicted time to next failure is greater than the specified value). This graph is for the Shuttle operational increment OIC In this example the RCM is in the DESIRED region at all values of  $t_n$ .

# **Approach to Prediction**

In order to support the reliability goal and to assess the risk of deploying the software, various reliability and quality predictions are made during the test phase to validate that the software meets requirements. For example, suppose the software reliability requirements state the following: 1) ideally, after testing the software for total test time t, the predicted remaining failures shall be less than one; 2) if the ideal of 1) cannot be achieved due to cost and schedule constraints, time to next failure, predicted after testing for total test time t, shall exceed the mission duration; and 3) the risk of not meeting 1) and 2) shall be assessed. Thus, this approach uses a software reliability model to predict the following: 1) maximum failures, remaining failures, and operational quality (as defined in the next section); 2) time to next failure (beyond the last observed failure); 3) total test time necessary to achieve required levels of remaining failures (fault) level, operational quality, and time to next failure; and 4) tradeoffs between increases in levels of reliability and quality with increases in testing (i.e., cost of testing).

An important concept to note is that reliability will be

measured during test; that is, failure data will be collected for two purposes: 1) to verify that the observed data conform to the reliability specified during design and 2) to provide data for reliability parameter estimation. With regard to 1), the observed time to next failure can be compared to the specified quantity. However, in contrast, observed remaining failures and maximum failures have no meaning because we don't know how many remaining failures (faults) there are at a given time during the life of the software and we don't know the maximum failures that will have occurred at the end of the life of the software. Thus remaining failures and maximum failures only have meaning as predicted quantities. However, we can make approximations to these quantities for model validation purposes (see the Summary of Predictions section).

### **Prediction Equations**

In order to consider the risk of deploying the PASS, various predictions have been made based on the Schneidewind Software Reliability Model [1, 8, 9, 10], one of the four models recommended in the ANSI/AIAA Recommended Practice for Software Reliability [1]. The equations are derived in the next section. They have been applied to analyze the reliability of the PASS based on the approach recommended herein. The Statistical Modeling and Estimation of Reliability Functions for Software (SMERFS) [4] is used for all predictions except t, which is not implemented in SMERFS.

Because the PASS is run continuously, around the clock, in simulation, test, or flight, "time" refers to continuous execution time and *total test time* refers to execution time that is used for testing. Failure count intervals are equal length periods of continuous execution time.

In the following equations parameter  $\alpha$  is the failure rate at the beginning of interval s; parameter  $\beta$  is the negative of the derivative of failure rate divided by failure rate (i.e., relative failure rate); t is the last interval of observed failure data; s is the starting interval for using observed failure data in parameter estimation that provides the best estimates of  $\alpha$  and  $\beta$  and the most accurate predictions [8];  $X_{s-1}$  is the observed failure count in the range [1,s-1];  $X_{s,t}$  is the observed failure count in the range [s,t]; and  $X_t = X_{s-1} + X_{s,t}$ . Failures are counted against operational increments (OIs). Data from four Shuttle OI's, designated OIA, OIB, OIC, and OID are used in this analysis example.

Cumulative Failures. When estimates are obtained for the parameters  $\alpha$  and  $\beta$ , with s as the starting interval for using observed failure data, the predicted failure count in the range  $\{s,t\}$  is obtained:

$$F_{s,t} = (\alpha/\beta)[1 - \exp(-\beta((t-s+1)))]$$
(5)

Furthermore, if  $X_{s-1}$ , the observed failure count in the range [1,s-1], is added to equation (5), the predicted *failure count in the range* [1, t] is obtained:

$$F(t)=(\alpha/\beta)[1-\exp(-\beta((t-s+1)))]+X_{s-1}$$
 (6)

Failures in an Interval Range. Let  $t=t_2$  and subtract  $X_{t_1}=X_{s-1}+X_{s,t_1}$ , the observed failure count in the range  $[1,t_1]$ , from equation (6), then obtain the predicted failure count in the range  $[t_1,t_2]$ :

$$F(t_1,t_2) = (\alpha/\beta)[1 - \exp(-\beta((t_2-s+1)))] - X_{s+1}$$
 (7)

**Maximum Failures.** Let  $t\to\infty$  in equation (6) and obtain the predicted failure count in the range  $[1,\infty]$  (i.e., maximum failures over the life of the software):

$$F(\infty) = \alpha/\beta + X_{\bullet-1} \tag{8}$$

**Remaining Failures.** To obtain predicted *remaining failures* r(t) at time t, subtract  $X_t = X_{s-1} + X_{s-1}$  from equation (8):

$$r(t) = (\alpha/\beta) - X_{t} = F(\infty) - X_{t}$$
(9)

r(t) can also be expressed as a function of *total test time*  $t_t$  by substituting equation (5) for  $X_{s,t}$  in equation (9) and letting  $t=t_t$ :

$$\mathbf{r}(\mathbf{t}_{t}) = (\alpha/\beta)(\exp{-\beta[\mathbf{t}_{t} - (\mathbf{s} - 1)]}) \tag{10}$$

Fraction of Remaining Failures. If equation (9) is divided by equation (8), fraction of remaining failures, predicted at time t is obtained:

$$p(t)=r(t)/F(\infty) \tag{11}$$

Operational Quality. The operational quality of software is the complement of p(t). It is the degree to which software is free of remaining faults (failures), using the assumption that the faults that cause failures are removed. It is predicted at time t as follows:

$$Q(t)=1-p(t) \tag{12}$$

Total Test Time to Achieve Specified Remaining Failures. The predicted *total test time* required to achieve a specified *number of remaining failures* at t<sub>t</sub>, r(t<sub>t</sub>), is obtained from equation (10) by solving for t<sub>t</sub>:

$$\mathbf{t_{t}} = [\log[\alpha/(\beta[\mathbf{r}(\mathbf{t_{t}})])]/\beta + (s-1)$$
(13)

**Time to Next Failure.** By substituting  $t_2$ =t+T<sub>F</sub>(t) in equation (7), letting  $t_1$ =t, defining F<sub>t</sub>=F(t,t+T<sub>F</sub>), and solving for T<sub>F</sub>(t), the predicted *time for the next F*, failures to occur, when the current time is t, is obtained:

$$T_{\mathbf{F}}(t)=[(\log[\alpha/(\alpha-\beta(X_{\mathbf{s},t}+F_{\mathbf{t}})])/\beta]-(t-s+1)$$
 for  $(\alpha/\beta)>(X_{\mathbf{s},t}+F_{\mathbf{t}})$  (14)

The terms in  $T_{\rm F}(t)$  have the following definitions:

t: Current interval;

X<sub>s</sub>.: Observed failure count in the range [s,t]; and

F<sub>t</sub>: Given number of failures to occur after interval t.

Equations (5)--(11) and (14) are predictors of reliability that can be related to safety or, as in the Shuttle example, the error-free condition of the software; equation (13) represents the predicted total test time required to achieve stated reliability goals. If a quality requirement is stated in terms of fraction of remaining failures, the definition of Q as Operational Quality, equation (12), is the degree to which the software meets specified requirements [7]. For example, if a reliability specification requires that software is to have no more that 5% remaining failures (i.e., p=.05, Q=.95) after testing for a total of t<sub>t</sub> intervals, then a predicted Q of .90 would indicate the degree to which the software meets the requirement.

#### Relating Testing to Reliability and Quality

#### Predicting Total Test Time and Remaining Failures.

The tradeoff between testing and reliability can be analyzed by first using equation (8) to predict maximum failures  $(F(\infty)=11.76 \text{ for } Shuttle \ OIA)$ . Then, using given values of p and equation (11) and letting  $t=t_t$ ,  $r(t_t)$  is predicted for each value of p. The values of  $r(t_t)$  are the predictions of remaining failures after the OI has been executed for total test time  $t_t$ . Next the values of  $r(t_t)$  and equation (13) are used to predict corresponding values of  $t_t$ . The results are shown in Figure 5, where  $r(t_t)$  and  $t_t$  are plotted against p for OIA. Note that required total test time  $t_t$  rises very rapidly at small values of p and  $r(t_t)$ . Also note that the maximum value of p on the plot corresponds to  $t_t=18$  and that smaller values correspond to future values of  $t_t$  (i.e.,  $t_t>18$ ).

Predicting Operational Quality. Similarly, the tradeoff between testing and quality can be analyzed by using equation (12), which is a useful measure of the *operational quality* of software because it measures the degree to which faults have been removed from the software (using the assumption that the faults that cause failures are removed), relative to predicted *maximum failures*. This type of quality is called *operational* (i.e., based on executing the software) to distinguish it from static quality (e.g., based on the complexity of the software). Using given values of p and equations (11) and (12) and letting  $t=t_t$ ,  $r(t_t)$  and Q are computed, respectively. The values of  $r(t_t)$  are then used in equation (13) to compute  $t_t$ . Like equation (12), equation (13) has the

asymptotic property of a great amount of testing required to achieve high levels of quality.

## **Making Reliability Decisions**

In making the decision about how long to test, t<sub>t</sub>, the reliability criteria and risk assessment approach can be applied. Table 1 is used to illustrate the process. For t<sub>t</sub>=18 (when the last failure occurred on OIA), r<sub>c</sub>=1, and t<sub>m</sub>=8 days (.267 intervals), remaining failures, RCM for remaining failures, time to next failure, RCM for time to next failure, and operational quality are shown. These results indicate that criterion 2 is satisfied but not criterion 1 (i.e., CRITICAL with respect to remaining failures); also operational quality is low.

By looking at Table 1, it can be seen that if remaining failures r(18) are reduced by 1 from 4.76 to 3.76 (non-integer values are possible because the predictions are mean values), the predicted time to next failure that would be achieved is  $T_{\rm r}(18)=3.87$  intervals. These predictions satisfy *criterion 2* (i.e.,  $T_{\rm F}(18)=3.87>t_{\rm m}=.267$ ) but not criterion 1 (i.e.,  $r(18)=4.76>r_0=1$ ). Note also in Table 1 that fraction of remaining failures p=1-Q=.40 at r(18)=4.76. Now, if testing is continued for a total time t=52 intervals, as shown in Table 1, and remaining failures are reduced from 4.76 to .60, the predicted time to next 4.16 failures that would be achieved is 33.94 (34, rounded) intervals. This corresponds to t=18+34=52 intervals. That is, if testing is continued for an additional 34 intervals, starting at interval 18, another 4.16 failures would be expected. These predictions now satisfy criterion 1 because r(52)=.60<re=1. Note also in Table 1 that fraction of remaining failures p=1-O=.05 at r(52)=.60. Using the converse of the relationship, provides another perspective, where, if testing is continued for an additional T<sub>F</sub>=34 intervals, starting at interval 18, the predicted reduction in remaining failures that would be achieved is 4.16 or r(52)=.60.

Lastly, Figure 6 shows the Deployment Decision, relevant to the Shuttle (which could be the Launch Decision relative to the Shuttle), where remaining failures are plotted against total test time for OIA. With these results in hand, the software manager can decide whether to deploy the software based on factors such as predicted remaining failures, as shown in Figure 6, along with considering other factors such as the trend in reported faults over time, inspection results, etc.. If testing were to continue until t=52, the predictions in Figure 6 and Table 1 would be obtained. These results show that criterion 1 is now satisfied (i.e., DESIRED) and operational quality is high. Figure 6 also shows that at t=52, further increases would not result in a significant increase in reliability. Also note that at t=52 it is not feasible to make a prediction of T<sub>r</sub>(52) because the predicted remaining failures is less than one.

### **Summary of Predictions**

Table 2 shows a summary of remaining and maximum failure predictions compared with actual failure data, where available, for OIA, OIB, OIC, and OID. The purpose of this analysis is to validate the model for Shuttle applications. Because actual remaining and maximum failures are unknown, the assumption is used: that remaining failures are "zero" for those OI's (B, C, and D) that were executed for extremely long times (years) with no additional failure reports; correspondingly, for these OI's, the assumption is used: that maximum failures equals total observed failures.

Table 3 shows a summary of total test time and time to next failure predictions compared with actual execution time data, where available, for OIA, OIB, OIC, and OID.

#### Lessons Learned

Several important lessons have been learned from our experience of twenty years in developing and maintaining the PASS, which you could consider for adoption in your SRE process:

- 1) No one SRE process method is the "silver bullet" for achieving high reliability. Various methods, including formal inspections, failure modes analysis, verification and validation, testing, statistical process management, risk analysis, and reliability modeling and prediction must be integrated and applied.
- 2) The process must be continually improved and upgraded. For example, recent experiments with software metrics have demonstrated the potential of using metrics as early indicators of future reliability problems. This approach, combined with inspections, allows many reliability problems to be identified and resolved prior to testing.
- 3) The process must have feedback loops so that information about reliability problems discovered during inspection and testing is fed back not only to requirements analysis and design for the purpose of improving the reliability of future products but also to the requirements analysis, design, inspection and testing *processes* themselves. In other words the feedback is designed to improve not only the product but also the processes that produce the product.
- 4) Given the current state-of-the-practice in software reliability modeling and prediction, practitioners should *not* view reliability models as having the ability to make highly accurate predictions of future software reliability. Rather, software managers should interpret these predictions in two significant ways: a) providing increased confidence, when used as part of an integrated SRE process, that the software is safe to deploy; and 2) providing bounds on the reliability of

the deployed software (e.g., high confidence that in operation the time to next failure will exceed the predicted value and the predicted value will safely exceed the mission duration).
